Abstract

The Neoproterozoic strata of the Sichuan Basin is a key target for oil and gas. To evaluate the hydrocarbon evolution and its relationship with tectonic events in the Micang Shan Uplift, northernmost Sichuan Basin, we apply solid bitumen geochemistry (bitumen reflectance and fluorescence) and rhenium-osmium (Re-Os) geochronology.

The geochemistry of the solid bitumen indicates it is highly mature pyrobitumen that formed contemporaneously with dry gas generation during oil thermal cracking. The pyrobitumen is enriched in both Re (~106 - 191 ppb) and Os (~3030 - 5670 ppt). The Re-Os isotope data imply an Early Jurassic date for pyrobitumen formation, which coincides well with age estimates from fluid inclusion data and basin modelling. The Re-Os date for pyrobitumen formation coupled with previously presented AFT analysis show that exhumation of the Neoproterozoic strata occurred during the Cretaceous in the Micang Shan Uplift. This extensive uplift led to the erosion of any potential gas reservoirs and surface exposure of bitumen-bearing Neoproterozoic strata. In contrast, the more southern and central portions of the Sichuan Basin have experienced less severe exhumation and as result Neoproterozoic sourced gas systems are present. This study shows that through the combined application of Re-Os and AFT methodologies the timing of gas generation and subsequent erosion of any

potential gas reservoirs in the Micang Shan Uplift, northern Sichuan Basin can be quantified. Moreover, the Re-Os and AFT data illustrate the potential to constrain the timing of gas generation in petroleum systems worldwide.

Key words: Solid bitumen, Re-Os geochronology, Petroleum evolution, Gas generation, Sichuan Basin

1. Introduction

Hydrocarbon (oil and gas) production and shows sourced from or reservoirs in Proterozoic to Cambrian successions occur worldwide, and are an important economic resource (Bhat et al., 2012; Craig et al., 2009; Ghori et al., 2009). For example, the Lena–Tunguska Proterozoic–Early Cambrian (microfossils and K-Ar dates on glauconites show the oldest date is 590 - 680 Ma) petroleum province, which includes the Lena Trough, the Kansk Basin, the Tunguska Basin, and the Sukhana Basin, located on the Siberian Craton, northern Russia, has a total estimated resource of 2 Bbbl (billion barrels) of oil and 83 Tcf (trillion cubic feet) of gas (Ghori et al., 2009; Meyerhoff, 1982). In addition, three potentially economically viable Proterozoic oil and gas systems have been found in Australia (McArthur, Urupungan and Centralian), which have a combined estimated resource of over 2 Bbbl of oil and 10 Tcf of gas (Bradshaw et al., 1994; Jackson et al., 1986; Munson, 2014). In the poorly explored Taoudenni Basin of North Africa, two deep exploration wells (Abolag-1 and Ouasa-1) have intersected a Neoproterozoic reservoir. A short duration open hole test on Abolag-1 well provided an estimated gas resource of 48000 scf

(standard cubic feet) per day (Lottaroli et al., 2009). In China, the Sichuan Basin is another potentially prolific Proterozoic-Cambrian petroleum sourced area with an estimated resource of 26.2 Bbbl of oil and ~180 Tcf of gas (Fig. 1) (Ghori et al., 2009; Li et al., 2001; Zhang and Zhu, 2006; Zou et al., 2014a). Specific examples in the Sichuan Basin include the Weiyuan and Anyue gas fields, which are both sourced and reservoirized in Neoproterozoic to Cambrian sedimentary rocks, and contain ~1.4 and ~15.4 Tcf of gas, respectively (Fig. 1) (Korsch et al., 1991; Li et al., 2015; Ma et al., 2010).

It is considered that much of the “easy exploration” around the world has been exhausted, and as a result industry is being forced to focus on more challenging exploration targets, such as Neoproterozoic-Cambrian strata (Bhat et al., 2012; Craig et al., 2009; Ghori et al., 2009). However, such systems typically possess significantly more complex geological evolution compared with conventional Phanerozoic petroleum systems, and as a result the exploration risk is greatly increased (Ghori et al., 2009; Katz and Everett, 2016). Further, as a direct outcome of multiple tectonic events, potential reservoirs have experienced high temperatures and pressures as well as uplift and subsidence. These factors, coupled with low quality seismic profiles, resulted in six decades of exploration to find the Anyue giant gas field following the discovery of the Weiyuan gas field in the Sichuan Basin (Wei et al., 2008; Zou et al., 2014a). Thus, in order to improve the exploration success rate of Proterozoic-Cambrian petroleum systems, a better understanding of their evolution, including timing of hydrocarbon generation, migration, accumulation and even trap

destruction, is needed.

Basin modelling, as well as, hydrocarbon fluid inclusion analysis are widely used methods to constrain hydrocarbon evolution history (Angevine et al., 1990; Gonzaga et al., 2000; Parnell et al., 1996; Parnell et al., 2000; Schneider, 2003). However, imperfect kinetic models and poorly constrained parameters, such as the paleo-geothermal gradient, pressure and properties of the strata, hamper the accuracy of proposed evolution histories (Braun and Burnham, 1992; Roberts et al., 2004; Tissot et al., 1987). Since the 1980s, isotopic dating methods, for example, authigenic K-Ar illite (Dong et al., 1995; Lee et al., 1985; Meunier et al., 2004; Tohver et al., 2008), Ar-Ar K-feldspar (Mark et al., 2010), and Ar-Ar quartz fluid inclusion (Qiu et al., 2011), have all been shown to yield valuable information with regard to the timing of hydrocarbon generation and migration. However, authigenic illite K-Ar and Ar-Ar could only yield the maximum timing of hydrocarbon emplacement, given the challenge to isolate ^{40}Ar from samples (Dong et al., 1995; Mark et al., 2010). Additionally, Ar-Ar dating of quartz fluid inclusions requires samples to be enriched in gas-liquid inclusions. The latter, combined with the analytical challenge of isolating the Ar from the gas inclusions has limited the available results (Liu et al., 2011; Qiu et al., 2011). Compared to K-Ar and Ar-Ar dating on associated minerals, for example illite, K-feldspar and quartz fluid inclusions, rhenium-osmium (Re-Os) dating directly of the oil or solid bitumen, has shown promise to determine the absolute timing of hydrocarbon (oil and gas) generation (Cumming et al., 2014; Finlay et al., 2011; Ge et al., 2016; Georgiev et al., 2016; Lillis and Selby, 2013; Liu et al., 2017; Selby and

114 Creaser, 2005; Selby et al., 2005; Selby et al., 2007).

115 Solid bitumen can form at different evolutionary stages within a petroleum system
116 (Jacob, 1989; Lewan, 1985; Meyer and De Witt Jr, 1990; Stasiuk, 1997; Wu et al.,
117 2000). For example, asphalt and gilsonite are associated with crude oil generation,
118 with impsonite and high maturity pyrobitumen considered to be related to crude oil
119 decomposition or gas formation (Bernard et al., 2012; Lewan, 1997; Stasiuk, 1997;
120 Wu et al., 2000; Xiao et al., 2007; Zhang and Li, 1999). To date, the available Re-Os
121 data are for solid bitumen from the Polaris Mississippi Valley-type Zn-Pb deposit,
122 Canada and the Northern Longmen Shan Thrust Belt, Southwest China, gilsonite from
123 the Green River petroleum system in the Uinta Basin, western USA, and pyrobitumen
124 from the Majiang-Wanshan reservoir, South China (Cumming et al., 2014; Ge et al.,
125 2016; Ge et al., 2017; Selby et al., 2005).

126 The complex tectonic and hydrocarbon evolution of the Sichuan basin has resulted in
127 highly debated timing and source models for many of hydrocarbon systems (e.g., the
128 Weiyuan, Ziyang, Anyue and Puguang gas fields (Ma et al., 2007; Wei et al., 2008;
129 Zhu et al., 2006)). Present research based on both structural and sedimentary analysis
130 in the Sichuan basin suggests that the Late Silurian (ca. 420 Ma), Permian (ca. 250
131 Ma) and Early Jurassic (ca.180 Ma) could be key time intervals for both oil and gas
132 generation (Li et al., 2016; Sun, 2008; Wang and Wang, 2011; Wang, 2015). Located
133 in the north of the Sichuan Basin is the Micang Shan Uplift (Liu et al., 2015).
134 Compared with the central or northwest Sichuan Basin, the Micang Shan Uplift has
135 undergone additional tectonism since the Cretaceous (Chang et al., 2010; Sun et al.,

2011a; Sun et al., 2011b; Yang et al., 2013) . Thrust tectonics during the Yanshan (ca. 150 Ma) or Himalayan orogeny (ca. 60Ma) resulted in the uplift of both Cambrian and Neoproterozoic strata to the surface (Dai et al., 2009).

Here we present solid bitumen Re-Os geochronology of the Micang Shan Uplift, coupled with bitumen reflectance, fluorescence analysis and previously published apatite fission track data (AFT age and thermal history modelling) to determine the Proterozoic-Cambrian hydrocarbon evolution process of the Micang Shan Uplift in the northern sector of the Sichuan Basin. Our data has potential implications for understanding the Proterozoic-Cambrian hydrocarbon evolution of other regions in the Sichuan Basin, and illustrates that the combined application of solid bitumen Re-Os geochronology and apatite fission track (AFT) analysis can provide valuable chronological data for petroleum evolution. In addition to Micang Shan Uplift, high maturity solid bitumen (pyrobitumen) occurs worldwide, e.g., in the Alberta Basin, Canada (Stasiuk, 1997), the Dahoney Basin, Nigeria (Meyer and De Witt Jr, 1990) and the Basque-Cantabrian Basin, Spain (Agirrezabala et al., 2008), this work are also potentially helpful for the hydrocarbon exploration worldwide.

2. Geological setting

The Micang Shan Uplift occurs along the northern margin of the Upper Yangtze block and comprises the northernmost sector of the Sichuan Basin, occupying an area of ~ 4500 km² (1737 mi²) (Li et al., 2014). The Micang Shan Uplift is bordered by three different orogenic belts (Longmen Shan, Hannan Uplift, and the Daba Shan Orogeny),

which lie to the west, northeast and east, respectively (Fig. 2) (Liu et al., 2015; Wang et al., 2014). From north to south, the Micang Shan Uplift is divided into three structural belts: the Basement Thrust Belt, the Submountain Fault-Fold Belt, and the South Foreslope (Huang, 2013). The entire Micang Shan Uplift records at least three orogenic events: 1) the Caledonian (ca. 480 Ma), 2) the Indosinian (ca. 200 Ma), and 3) the Yanshan (ca. 150 Ma) orogenies (Dong et al., 2012; Dong et al., 2011; Sun et al., 2011a; Sun et al., 2011b; Tian et al., 2012; Yang et al., 2013) (Fig. 3).

Structurally the Micang Shan Uplift represents a regional-scale anticline that comprises basement Neoproterozoic metavolcanics and granite, with overlying Neoproterozoic, Paleozoic (Cambrian to Silurian and Permian) and Mesozoic (Triassic and Jurassic) marine carbonate and clastic rocks (Qi et al., 2004; Wang et al., 2008) (Fig. 3). Solid bitumen is widely distributed within the Micang Shan Uplift in the Neoproterozoic Dengying Formation (Dai et al., 2009). The Dengying Formation occurs over an area of 8500 km² (3281 mi²), and has a maximum thickness of ~500 m (1640 ft), with an average thickness of ~100 m (328 ft). The estimated total solid bitumen reserves in the Dengying Formation of the Micang Shan Uplift and adjacent area is about 12.5 billion tons, which is equivalent to ~150 Bbbls of crude oil (Dai et al., 2009). The solid bitumen exists as pyrobitumen as a result of thermal cracking of pre-existing hydrocarbons (this study; see section 4 and 5 for details). Given the total abundance of pyrobitumen in the Micang Shan Uplift, the generated gas volume during pyrobitumen formation is determined to have exceeded 400 Tcf (Liu et al., 2015). As a result of tectonic uplift since the Cretaceous, all cap rocks in the Micang

Shan Uplift have been exhumed (Chang et al., 2010; Dai et al., 2010). In contrast, cap rocks are well developed in the more southern sectors of the Sichuan Basin. For example, the Cambrian and Silurian, and Triassic and Jurassic units are local seals in the Tongjiang and Bazhong regions (Liu et al., 2015). The Early Cambrian Qiongzhusi Formation is considered to be the principal source of the pyrobitumen in the Sichuan Basin, according to current biomarker analysis of the solid bitumen (though high maturity may affect the parameters) and potential source rocks (Liu et al., 2015; Zhang, 2013), element geochemistry evaluation of the potential sources (Cao et al., 2014) and the similar carbon isotope values of the Cambrian shale ($\delta^{13}\text{C} \sim 27.2 \text{ ‰}$) and pyrobitumen ($\delta^{13}\text{C} \sim 27.5 \text{ ‰}$).

3. Samples and methodology

The solid bitumen samples analysed in this study are representative of occurrences along the southern margin of the Micang Shan Uplift (Fig. 2). Solid bitumen occurs as accumulations as small as ~1 cm (0.39 in) long and ~ 0.2 - 0.5 cm (0.08 - 0.20 in) wide, and more commonly as ~ 3 - 5 cm (1.18 - 1.97 in) long and ~ 2 - 3 cm (0.79 - 1.18 in) wide (Fig. 4) within pores and fractures that are found widely distributed in the dolomite reservoir of the Dengying Formation. In hand specimens, the solid bitumen possesses a smooth and vitreous surface. Under the microscope, the bitumen is shown to occur intergrown with calcite and quartz, and to be predominantly hosted in hairline fractures or vugs. Eleven samples were collected from seven different locations. From east to west, these locations are the Jiulingzi(JLZ), Nanmushu(NMS),

202 Mayuan(MY), Zhujiaba(ZJB), Kongxigou(KXG), Huitan(HT) and Yangba(YB) areas.

203 The distance between each sample location is ~ 5 to 8 km (3 – 5 mi) (Fig. 2) (see

204 Table 1 for latitude and longitude data). All the samples were collected from surface

205 exposures and from similar stratigraphic levels within the Denying Formation, which

206 dips at ~ 40° towards the southeast.

207 The solid bitumen fluorescence analyses were conducted at the Wuxi Institute of

208 Petroleum Geology, SINOPEC. The solid bitumen-bearing limestones were first cut

209 and polished into standard thin sections (~ 0.03 - 0.05 mm). The solid bitumen was

210 examined using a Nikon ECLIPSE LV100N POL polarizing microscope under

211 transmitted, reflected and fluorescent light at room temperature. The light source was

212 a 100 W mercury lamp, with a digital photomicrography system. Bitumen reflectance

213 (BRo, %) of incident light under oil immersion was used to assess the thermal

214 maturity of samples. The reflectance microscope measures the amount of reflected

215 light relative to the incident light and expresses this ratio as a percentage. The BRo

216 value is obtained according to the formula, $BRo = (N - Ne)^2 + K^2 / (N + Ne)^2 + K^2$,

217 where Ne is the refraction index of the oil used, N is the sample refraction, and K is

218 the absorption coefficient (Zhang, 1988). The solid bitumen reflectance analyses were

219 conducted at the Wuxi Institute of Petroleum Geology, SINOPEC, based on the

220 method of (Zhang, 1988). The solid bitumen was first ground to ~ 0.15 mm, then

221 mixed with resin and finally compressed into a cylindrical form. One surface of the

222 cylinder was polished and immersed into oil with a refraction index (Ne) of 1.518.

223 The sample refraction (N) was measured using a monochromatic light with a

224 wavelength of 546 nm and a microscopy spectrophotometer (version: MPV-III,
225 806(5)). The BRo value is determined through an average of 30 measured points in
226 each sample.

227 The Re and Os isotopic analysis of the solid bitumen samples were analysed at the
228 Laboratory for Source Rock and Sulfide Geochronology and Geochemistry (a
229 member of the Durham Geochemistry Centre) at Durham University following
230 published analytical procedures (e.g. Selby et al., 2005; Selby et al., 2007).

231 Approximately 0.2 - 1.0 g bitumen was first separated from the limestone rocks
232 without metal contact and crushed to ~ 1 mm grains using an agate pestle and mortar.

233 Approximately 100 - 200 mg of bitumen were dissolved and equilibrated with a
234 known amount of ^{185}Re and ^{190}Os spike solution by inverse *aqua-regia* (3 ml HCl and
235 6 ml HNO_3) in a Carius tube for 24 hours at 220°C. Osmium was isolated and further
236 purified from the inverse *aqua-regia* by CHCl_3 solvent extraction at room temperature

237 and micro-distillation, respectively. The Re was isolated using HCl- HNO_3 based
238 anion chromatography. The purified Re and Os were loaded on Ni and Pt filaments,
239 respectively, and analyzed using Negative Ion Thermal Ionization Mass Spectrometry

240 (N-TIMS). Rhenium was measured using Faraday collectors and Os in peak hopping

241 mode using a secondary electron multiplier (SEM). Measured Re and Os ratios were

242 corrected for oxide contribution and mass fractionation using $^{185}\text{Re}/^{187}\text{Re} = 0.59738$

243 (Gramlich et al., 1973) and $^{192}\text{Os}/^{188}\text{Os} = 3.08261$, spike and blank contributions. All

244 data were blank corrected based on the total procedural blanks values of Re ($1.6 \pm$

245 0.025 pg) and Os (0.05 ± 0.004 pg), with an average $^{187}\text{Os}/^{188}\text{Os}$ ratio of $\sim 0.22 \pm 0.06$

(n = 4). All uncertainties include the propagated uncertainty in the standard, spike calibrations, mass spectrometry measurements, and blanks. The analyses presented in this study were conducted prior to using DROsS as the in-house control solution (Nowell et al., 2008) at Durham. The $^{187}\text{Os}/^{188}\text{Os}$ values of the Os standard solution AB2 during these studies were 0.1611 ± 0.0066 , with the $^{185}\text{Re}/^{187}\text{Re}$ values of the Re standard solution being 0.5984 ± 0.0002 . These values are in agreement with those previously published for AB2 and Re-std (Cumming et al., 2014; Finlay et al., 2011, 2012; Lillis and Selby, 2013; Rooney et al., 2012). The $^{185}\text{Re}/^{187}\text{Re}$ ratios for samples of this study were corrected for the measured difference of the $^{185}\text{Re}/^{187}\text{Re}$ value for Restd and the $^{185}\text{Re}/^{187}\text{Re}$ value of 0.59738 ± 0.00039 (Gramlich et al., 1973). The Re–Os data of this study are regressed using the program *Isoplot* V. 4.15 (Ludwig, 2008) using the ^{187}Re decay constant of $1.666 \times 10^{-11} \text{a}^{-1}$ (Smoliar et al., 1996). The input data contains $^{187}\text{Re}/^{188}\text{Os}$ and $^{187}\text{Os}/^{188}\text{Os}$ ratios with their total 2σ uncertainty and associated error correlation, Rho.

To further discuss the hydrocarbon and tectonic evolution of the Micang Shan Uplift, we have utilized the previously published Apatite Fission Track (AFT) data (n = 35) obtained from outcrop or borehole samples distributed over a north – south transect across the study area (Lei et al., 2012; Tian et al., 2012; Yang et al., 2013) (Fig. 2; Table. 2). In addition, thermal history modeling results (n = 15) in the study area are also utilized (Tian et al., 2012; Yang et al., 2013). These thermal history models are determined from eight Proterozoic granite, diorite or sandstone samples (MC01, MC02, MC25, NJ1T, NJ2T, NJ3T, NJ5T, NJ6T) located in the Micang Shan Uplift,

and seven Paleozoic - Mesozoic sandstone samples (MC03, MC05, MC11, NJ12T, NJ15T, NJ17T, HB1-4) that are distributed in the southern area of the Micang Shan Uplift, e.g., the Submountain Fault-fold Belt and the South Foreslope (Fig. 2; Table 2).

4. Results

The bitumen reflectance (BRo, %), which is used in a similar way as vitrinite reflectance (Ro, %), is an indicator of thermal maturity of bitumen, and has become a tool used in basin analysis (Bertrand, 1993; Riediger, 1993). The BRo values become higher with increasing hydrocarbon maturity. According to the linear relationship between BRo and Ro (Jacob, 1989; Landis and Castaño, 1995; Schoenherr et al., 2007), bitumen at various maturity levels has different BRo values. For example, immature solid bitumen possess BRo values of < 0.25, with mature and over-mature solid bitumen being characterised by BRo values of ~ 1.1 and > 1.7 (Jacob, 1989; Landis and Castaño, 1995; Schoenherr et al., 2007). The BRo values of 3.25 to 4.08 (Table 1) for the five solid bitumen samples from the Micang Shan Uplift characterise the solid bitumen as thermally over-mature.

Ultraviolet fluorescence of the hydrocarbons (bitumen and oil) is also a useful tool for evaluating hydrocarbon maturity. With increasing maturity, the fluorescence color will gradually change from yellow-green, to brownish and finally to colorless (Chen, 2014; Jacob, 1989; Shi et al., 2015). The microscopic features of the solid bitumen samples (NMS and JLZ) from the Micang Shan Uplift are shown in Figure 5. The

reservoir rocks are mainly composed of dolomite, containing pelletoid or granular-mosaic solid bitumen within fissures or between grains, with the solid bitumen possessing no fluorescence, thus characterizing the bitumen as highly mature (Fig. 5). Collectively, the organic petrography implies that the solid bitumen from the Micang Shan Uplift are pyrobitumen which formed through thermal cracking under high temperature environment, $\geq 140^{\circ}\text{C}$ (Dieckmann et al., 1998; Pepper and Corvi, 1995; Tsuzuki et al., 1999; Waples, 2000).

The Re and Os abundances of the solid bitumen samples range from ~ 106 to 191 ppb, and ~ 3030 to 5670 ppt, respectively (Table 1). These Re and Os abundances are significantly higher than those of average upper crustal values (Re = 0.198 ppb and Os = 31 ppt) (Esser and Turekian, 1993; Rudnick and Gao, 2003), but similar to values previously reported for bitumen and organic-rich sedimentary rocks (Cohen et al., 1999; Ge et al., 2016; Georgiev et al., 2016; Lillis and Selby, 2013; Ravizza and Turekian, 1992; Rooney et al., 2010; Xu et al., 2009a; Xu et al., 2014). The $^{187}\text{Re}/^{188}\text{Os}$ and $^{187}\text{Os}/^{188}\text{Os}$ values of the solid bitumen range from ~ 166 to 340 , and ~ 2.82 to 3.74 , respectively (Table 1). All the Re-Os data yield a Model 3 (assumes that the scatter about the best fit line is a combination of the assigned uncertainties and an unknown, but normally distributed variation in the $^{187}\text{Os}/^{188}\text{Os}$ values (Ludwig, 2008)) date of 239 ± 150 Ma ($n = 11$, Mean Squared Weighted Deviation (MSWD) = 398) (Fig. 6A), with an initial $^{187}\text{Os}/^{188}\text{Os}$ composition of 2.29 ± 0.64 (Table 1).

All the 35 AFT dates range from 123.5 ± 6.0 to 8.8 ± 1.3 Ma. The AFT dates are all younger than the intrusion or depositional ages of the sampled rocks, which indicate

that the date represents the timing of thermal resetting. The AFT dates overall show a trend to younger dates from north to south across the Micang Shan Uplift into the Sichuan Basin (Fig. 2). The eleven samples in the Micang Shan Uplift possess older dates (~ 64 - 124 Ma) with a mean age of ca. 102 Ma. Eighteen outcrop samples from the inner Sichuan Basin possess AFT dates from ca. 60 to 83 Ma, with an average of ca. 70 Ma. The AFT dates from borehole HB1 from north Sichuan Basin (Fig. 2), with the exception of the most-shallow sample, HB1-4, which has a date of ca. 73 Ma, possess considerably younger dates (ca. 9 - 26 Ma). The mean track length of the thirty-five samples varies between 10.0 ± 0.45 and 13.23 ± 0.10 μm . Similar to the AFT date distribution, a decrease in track length is observed for samples from north to south (Table 2). The decreasing trend, in both AFT age and track length, from north to south implies variable cooling histories across the Sichuan Basin.

The thermal history (time-temperature path) could provide a more detailed understanding of the tectonic evolution of the Micang Shan Uplift and inner Sichuan Basin. Fifteen samples, six of our own remodelled samples (MC01, MC02, MC03, MC05, MC11, MC25) and nine previous published results (Tian et al., 2012) are shown here (Fig. 7). The thermal history are remodelled using the HeFTy software (version 1.8.4) based on the fanning curvilinear annealing model (Ketcham, 2005), c-axis projection (Donelick et al., 1999), and initial mean track length ($L_0 = 16.0 \pm 0.8$ μm) (Shen et al., 2012). For each sample, 100,000 to several million paths were calculated until at least 500 'good' [T-t] paths were obtained (see (Yang et al., 2013) for the detailed modeling methodology). The thermal history modelling results of the

fifteen samples can be divided into two groups. Group 1 comprise samples ($n = 8$) from the Micang Shan Uplift. Although there are some minor differences, cooling between ca. 140 and 100 Ma, with a temperature decrease from ~120 to 60 °C (apatite partial annealing zone, APAZ) is revealed (Fig. 7). Group 2 comprise samples ($n = 7$) south of the study area and represent a cooling event between ca. 100 and 60 Ma, which implies that cooling to between ~120 and 60 °C in the more southern Sichuan Basin occurred ~40 myrs after that in the more northern Micang Shan Uplift (Fig. 7).

5. Discussion

5.1. Bitumen characteristics in the Micang Shan Uplift

Hydrocarbon evolution is a complex process that begins with diagenesis and the formation of the kerogen (Lewan, 1985; Tissot, 1984; Tissot and Welte, 1984). Solid bitumen, as a by-product of organic matter, exists through the entire hydrocarbon evolution process and records events such as hydrocarbon maturity, migration and accumulation pathways and the origin of the hydrocarbons (Wu et al., 2000). Processes, such as biodegradation, oxidation, phase-migration and thermal cracking, can lead to the formation of different types of solid bitumen (asphalt, gilsonite, grahamite, impersonite, anthroxolite, etc) (Jacob, 1989; Meyer and De Witt Jr, 1990; Rogers et al., 1974; Wu et al., 2000). The processes of oxidation, biodegradation, polymerization and devolatilization could result in the removal of the light hydrocarbons and form asphalt and gilsonite (Meyer and De Witt Jr, 1990). Phase-migration during hydrocarbon migration can lead to fluid differentiation

through precipitation and de-asphalting (Meyer and De Witt Jr, 1990), resulting in the formation of grahamite, which typically occurs as veins (Stevenson et al., 1990; Zhang and Li, 1999). Thermal cracking, controlled by time and high temperature (Dahl et al., 1999; Vandenbroucke et al., 1999), of all hydrocarbons (e.g., oil, asphalt, gilsonite and grahamite) can result in the generation of dry gas and high maturity pyrobitumen (impsonite, antraxolite) (Meyer and De Witt Jr, 1990; Rogers et al., 1974).

High maturity pyrobitumen formed by thermal cracking is insoluble in most organic solvents and possesses different physical and chemical features compared with solid bitumen (Jacob, 1989; Mancuso et al., 1989; Rogers et al., 1974; Wu et al., 2000; Zhang and Li, 1999). For example, the solid bitumen types asphalt and gilsonite are characterized by low bitumen reflectance ($B_{Ro} < 1.0\%$), high H/C atomic ratio (> 0.8), low T_{max} ($\sim 450\text{ }^{\circ}\text{C}$), and a yellow-green fluorescence colour. In contrast, the high maturity pyrobitumen types impsonite and anthroxolite possess high bitumen reflectance ($B_{Ro} > 2.0\%$), low H/C atomic ratio (< 0.6), high T_{max} ($\sim 500\text{ }^{\circ}\text{C}$), dark or no fluorescence, and contain high adamantane (3- + 4- methyl diamantane) concentrations (Fang et al., 2014; Hwang et al., 1998; Jacob, 1989; Shi et al., 2015; Wang et al., 2013; Yang et al., 2014).

All solid bitumen samples collected from the Micang Shan Uplift in this study have similar features (high bitumen reflectance ($B_{Ro} = 3.25 - 4.08$), no fluorescence and are insoluble in chloroform). Previous research in the Micang Shan Uplift area found that the bitumen was also characterized by high T_{max} values ($\sim 540\text{ }^{\circ}\text{C}$) (Huang,

2010). Collectively, the BRo values, fluorescence, Tmax, and lack of solubility in organic solvents characterise the solid bitumen in the Micang Shan Uplift as highly mature pyrobitumen. Although no gas reservoirs are known in the Micang Shan Uplift, the Neoproterozoic Weiyuan gas field in the Sichuan basin (Fig. 1), ~ 200 km (124 mi) south of the Micang Shan Uplift, possesses methane (CH₄) which comprises 85 % - 97 % of the total gas composition, with lesser amounts of nitrogen (N₂) (< 8%), carbon dioxide (CO₂) (< 5%) and ethane (C₂H₆)(< 1%) occupying the remaining components (Wei et al., 2008).

The molecular and isotope data (C₁-C₃ composition and $\delta^{13}\text{C}_1$ - $\delta^{13}\text{C}_3$ value) are useful tools for identifying the gas formation mechanism (Behar et al., 1992; Prinzhofer and Huc, 1995). During thermal cracking, the $\ln(\text{C}_2/\text{C}_3)$ value will increase, but the $\ln(\text{C}_1/\text{C}_2)$ and the $\delta^{13}\text{C}_2$ - $\delta^{13}\text{C}_3$ values will remain the same for the generated gas (Prinzhofer and Huc, 1995). The gas from both the Ziyang and Weiyuan gas fields in the Western Sichuan Basin display $\ln(\text{C}_1/\text{C}_2)$ values within a narrow range (~5.5 - 7.0), but the $\ln(\text{C}_2/\text{C}_3)$ ratio spans a much wider range (~1.0 - 6.5) (Liu et al., 2009).

These data indicate that the gas was formed by thermal cracking of a previously formed reservoired oil. This also suggests that oils reservoired in the rest of the Sichuan Basin could have also experienced thermal cracking to form highly mature pyrobitumen and the accumulations of dry gas (CH₄) where trapped.

5.2. Timing of oil thermal cracking in the Micang Shan Uplift

Source rock hydrous pyrolysis experiments show that, initially, bitumen quantities

increase as the amount of kerogen decreases, but as a result of increasing temperature, bitumen abundance decreases as it is cracked into liquid oil (Behar et al., 1991; Lewan, 1985). At higher temperatures (~ 360 °C), hydrous pyrolysis experiments show that the abundance of both bitumen and oil decrease in response to gas generation, as well as mass increasing in the source rock, which indicates the generation of high maturity pyrobitumen. The hydrous pyrolysis experiments indicate that the high maturity pyrobitumen and gas form contemporaneously during the last stages of hydrocarbon evolution. Further, recent studies on the thermal cracking of oil (Hill et al., 2003) and hydrocarbon composition numerical modelling (evolution of C₁₄₊ to C₁ compounds with time) in the Fahud Salt Basin, North Oman (Huc et al., 2000), found although pyrobitumen could form at the beginning of oil formation, the majority of the pyrobitumen formed together with the dry gas during the oil cracking event under high temperatures condition.

The Sichuan Basin contains more than 50 gas fields, which include the Ziyang, Weiyuan, Anyue and Puguang giant gas fields (Fig. 1) (Luo et al., 2013; Wei et al., 2008; Zou et al., 2014a). To date, there is still no agreement on the timing of the gas generation. Basin modelling of the Nanjiang area in the northern Sichuan Basin suggests that oil generation may have begun during the Late Cambrian to Ordovician (Wang and Wang, 2011). Following the exposure of the strata between the Devonian and Carboniferous, the entire Late Cambrian to Ordovician units of the Sichuan basin underwent rapid burial to ~7000 m (22,965 ft) between the Late Permian and Late Cretaceous (Fig. 8) (Liu et al., 2010; Ma et al., 2008; Wang and Wang, 2011).

Fluid inclusions can represent micron scale samples of the fluids (oil, gas and water) that flowed through and interacted with the host rocks during the evolution of a hydrocarbon system (Cooley et al., 2011; Haszeldine et al., 1984). Physical and chemical (pressure, temperature, fluid composition) conditions recorded by fluid inclusions within petroliferous basins have been widely applied to constrain both oil and gas migration and accumulation (Aplin et al., 1999; Bodnar, 1990; Bourdet et al., 2010; Cao et al., 2006; Oxtoby et al., 1995; Ping et al., 2017; Pironon, 2004; Teinturier et al., 2002). Fluid inclusion analysis in the Weiyuan Gas field, western Sichuan Basin, show that the homogenization temperatures of the aqueous fluid inclusions that are coeval with the gas-bearing fluid inclusions range from 108 - 212°C, with an average of 158°C (Tang et al., 2004). Furthermore, the fluid inclusion data from the Neoproterozoic Dengying Formation reservoir in the Micang Shan Uplift possess homogenization temperatures that fall between 105 and 245 °C, with 87% of the values being higher than 140 °C and average temperature at 180 °C (Fig. 8) (Wang, 2015). As to the few low temperature (< 120 °C) data, it may relate to early hydrocarbon migration during the Silurian (Zou et al., 2014b) or the post-entrapment modification (Okubo, 2005). Applying the generally high homogenization temperatures to basin burial models within the northern Sichuan Basin (Liu et al., 2015; Sun, 2008; Yuan et al., 2012), a gas migration event is suggested to have occurred between the Triassic and Jurassic.

All the Re-Os data of the pyrobitumen from the Micang Shan Uplift area yield a date of 239 ± 150 Ma ($n = 11$, initial $^{187}\text{Os}/^{188}\text{Os}$ (Osi) = 2.29 ± 0.64 , MSWD = 398). The

MWSD value obtained from the best-fit of all the Re-Os data suggests that the sample set have not fully met the criteria to obtain a precise isochron. For example, the entire sample set does not represent contemporaneous formation, or possess identical initial isotope compositions (Osi), or that the Re-Os systematics have been disturbed (Cohen et al., 1999; Kendall et al., 2009; Selby et al., 2007).

The percent deviation from the best-fit line of all the Re-Os data is illustrated in Figure 6B, which shows that samples HTB01, HTB02, JLZ4, YB01, KXG5 all show a large deviation (with the exception of sample KXG5 (~2.2%), > 4.4 %) from the best-fit line. Calculating the Osi value for each sample at 239 Ma (Osi₂₃₉), which is based on the Re-Os date of all eleven samples, shows that six samples (My601, My603, NMS955, NMS1030, NMS1068, ZJB01) possess very similar Osi₂₃₉ values (2.25 - 2.30), with the remaining five samples (KXG05, HTB01, HTB02, YB01, JLZ04) possessing either slightly less or more radiogenic Osi values (1.96 - 2.15, n = 2; 2.36 - 2.52, n = 3, respectively) (Table 1). The differences in the Osi values may relate to samples bearing different initial Os isotope compositions or samples that represent different generation ages, or have experienced disturbance to the Re-Os isotope system. We discuss these possibilities below.

As stated above, the Re-Os data for the six samples with similar Osi values (My601, My603, NMS955, NMS1030, NMS1068, ZJB01, which are the samples that show the least deviation of the best-fit line of all the data, Fig. 6B) yield a Model 1 (which considers that only the assigned uncertainties produce the scatter about the best-fit line (Ludwig, 2008)) Re-Os date of 184 ± 23 Ma (Osi = 2.50 ± 0.09 , MSWD = 1.0)

(Fig. 6C).

The remaining five samples plot in $^{187}\text{Re}/^{188}\text{Os}$ - $^{187}\text{Os}/^{188}\text{Os}$ space either above or below the ca. 184 Ma isochron (Fig. 6C). Of these samples, sample KXG05 possesses an Osi_{239} value of 2.36, which falls between the Osi_{239} values for HTB01 and HTB02 (2.49 - 2.52), and JLZ04 and YB01 (1.96 - 2.15), and will therefore not fall along any best-fit line (Fig. 6C). Although the isochron dates determined from two samples are not considered a robust reflection of the true geologic age (Ludwig, 2008), we note that the Re-Os data for samples HTB01 and HTB02, and JLZ04 and YB01, yield Re-Os dates that are within uncertainty of the dates determined from the 6 samples (205 ± 32 Ma, $\text{Osi} = 2.68 \pm 0.16$ and 173 ± 12 Ma, $\text{Osi} = 2.34 \pm 0.06$, respectively (Fig. 6C)).

In the Micang Shan Uplift, the pyrobitumen may suffer from biodegradation, water washing during the migration and uplift process since formation. Previous work (Lillis and Selby, 2013; Selby and Creaser, 2005) found that these effects do not appreciably disturb the Re-Os system. However, studies have found that the Re-Os system of the highly mature hydrocarbons, for example oil from Bighorn Basin, USA and bitumen from North Hebei Depression, China, may exhibit evidence of disturbance (Li et al., 2017; Lillis and Selby, 2013). Moreover, Re-Os isotope dating of pyrobitumen, which formed contemporaneously with dry gas, together with clastic AFT dating in the Majiang-Wanshan reservoir, South China show that the Re-Os date coincides with the timing related to gas generation and that the hydrocarbon thermal cracking event at temperatures of $>140^\circ\text{C}$ could reset the previous oil or asphaltene

Re-Os system (Ge et al., 2016).

In this study, Latest Triassic to the Middle Jurassic dates (ca. 205 – 173 Ma) derived from the Re-Os pyrobitumen data, especially the ~184 Ma date determined from six samples, from the Micang Shan Uplift agree well with previous basin modelling (Yuan et al., 2012) and the general temporal understanding of oil and gas accumulation events in the northern Sichuan Basin (Liu et al., 2015). This age agreement indicates that the Late Triassic to Jurassic is the key period for thermally cracking of oil in Neoproterozoic reservoirs that resulted in gas generation and high maturity pyrobitumen (Fig. 8). Thus, although we cannot rule out disturbance to the Re-Os systematics of the pyrobitumen, the variation in the Osi values shown by the sample set most likely represents variations in the Os isotope composition of the petroleum that thermally cracked to produce pyrobitumen during the Late Triassic to the Middle Jurassic, and or the protracted interval over which pyrobitumen and gas generation occurred in the Michan Shan Uplift.

5.3. Petroleum system evolution of northern Sichuan Basin

Since the Late Triassic collision between the north China block and Yangtze block, which lead to the formation of the Qinling Orogeny (Yin and Nie, 1993), the Micang Shan Uplift was affected by a continuous compressional tectonic regime, with the most severe event occurring during the Cretaceous when the Yangtze block collided with Qinling Orogeny (south margin of the north China block) (Sun et al., 2011a; Sun et al., 2011b). During this tectonism the E-W trending fold and thrust structures

510 between the Micang Shan Uplift and the inner Sichuan Basin were developed (Dong
511 and Santosh, 2016; Xu et al., 2009b).

512 The Group 1 AFT samples from the Micang Shan Uplift have older AFT ages (ca. 64
513 - 124 Ma) with the thermal history modeling showing that the samples entered the
514 apatite partial annealing zone (APAZ) between ca. 140 and 100 Ma, and cooled
515 through the APAZ before ca. 90 Ma. In contrast, Group 2 samples, which are
516 generally located at the transition zone between the Micang Shan Uplift and the inner
517 Sichuan Basin, possess slightly younger ages (ca. 60 - 83 Ma) and thermal history
518 modeling shows that the samples in this area pass in to the APAZ from ca. 100 to 60
519 Ma. The ~ 40 myr difference between both the AFT ages and the modeled cooling
520 and uplift models coincide well with the N-S propagation of the tectonic front (Hu et
521 al., 2012; Xu et al., 2009b). The AFT dates (ca. 60 to 124 Ma) and thermal history
522 models indicate a prolonged and continuous cooling and uplift during the Cretaceous
523 in the study area. Given the present-day thermal gradient (18 - 21°C/km (Hu et al.,
524 2000; Lu et al., 2005)) and the near surface temperature (~ 20°C), more than 5000 m
525 (16,404 ft) of strata is estimated to have been eroded as a result of the tectonic uplift
526 during the Cretaceous. However, the much younger AFT dates (ca. 9 - 26 Ma) from
527 the borehole HB1 (2594 – 4485 m (8510 – 14,714 ft) deep) in the Sichuan Basin
528 (Table 2) indicate that the Cretaceous tectonic event did not affect the sediments
529 within the inner Sichuan Basin, with the Jurassic and Triassic units currently at a
530 depth of more than 2500 m (8202 ft). Moreover, many gas fields that are reservoired
531 in the Neoproterozoic Dengying (Wei et al., 2008), Permian Changxing, and Triassic

Feixianguan formations (Ma et al., 2008) have been discovered within the central or southern Sichuan Basin (Fig. 1), which further prove that the tectonic event did not severely affect the inner Sichuan Basin. The presence of large quantities of pyrobitumen in the exposed and near-surface Neoproterozoic Dengying Formation and the absence of the Permian Changxing and Triassic Feixianguan formations in the northern Sichuan Basin (e.g., around the Micang Shan Uplift) suggest that ~ 5000 m (16,404 ft) of exhumation has occurred. Further evidence for uplift and erosion of the Proterozoic, Paleozoic and Mesozoic units of the Micang Shan Uplift is supported by a north-south paleocurrent direction (He et al., 1997; Meng et al., 2005), sandstone composition analysis (Dickinson et al., 1983; Liu et al., 2006), and detrital zircon U-Pb dates of the early Paleogene strata in the western Sichuan Basin (ca. 1800 – 130 Ma) (Jiang et al., 2013).

Integrating the pyrobitumen Re-Os data, AFT results (age and thermal history modeling) as well as previous basin models from the Micang Shan Uplift, permits the hydrocarbon evolution in the Micang Shan Uplift area to be quantitatively described as: (1) prior to the Caledonian Orogeny, Cambrian shales were buried to ~ 2500 m (8202 ft) depth throughout the whole Sichuan Basin and began to generate oil. However, subsequent uplift and exhumation during the Devonian to Carboniferous (Caledonian Orogeny) halted oil generation (Fig. 8a); (2) the Late Paleozoic-Early Mesozoic witnessed rapid sedimentation of the Permian to Triassic strata which resulted in the burial of the Neoproterozoic strata to ~ 7000 m (22,965 ft). Thermal cracking of the hydrocarbons under a high temperature environment (≥ 140 °C) as a

result of burial the generation of pyrobitumen and dry gas occurred during the Late Triassic to Middle Jurassic (Fig. 8b); and (3) since the Cretaceous, related to the N-S compression between the north China block and Yangtze block, the Micang Shan Uplift experienced rapid uplift and exhumation, bringing the pyrobitumen-bearing Neoproterozoic strata to the surface and also resulted in the loss of the any gas-bearing reservoirs. In contrast, in the central and southern sectors of the Sichuan Basin, Paleozoic and Mesozoic gas reservoirs have been preserved due to limited uplift during the Late Cretaceous (Fig. 8c).

6. Conclusions and Implications

High maturity pyrobitumen Re-Os analysis, as well as previous basin modelling of the North Sichuan Basin, indicate that hydrocarbon thermal cracking (dry gas generation from oil cracking) in the northern Sichuan Basin occurred during the Early Jurassic (ca. 184 Ma), as a result of a high temperature environment due to rapid sedimentation and burial during the Late Permian to Jurassic in the Sichuan Basin. The AFT data (age and thermal history) indicate that the prolonged Cretaceous Yanshan Orogeny resulted in significant uplift and exhumation (~ 5000 m (16404 ft)) and caused the loss of Paleozoic and Mesozoic gas reservoirs in the Micang Shan Uplift, with only pyrobitumen remaining in the Neoproterozoic strata. Previous work has shown that combined AFT and solid bitumen Re-Os geochronology on the Majiang-Wanshan reservoir, South China, has the potential to constrain the timing of oil cracking (pyrobitumen generation), and by inference, the

576 timing of gas generation (Ge et al., 2016). Although the AFT and Re-Os dates were
577 found to be similar in that work, the slightly older Re-Os date (ca. 80 Ma) compared
578 to the AFT date (ca. 70 Ma) suggest that the temperature condition of resetting of the
579 Re-Os systematics in hydrocarbons, specifically high maturity pyrobitumen, may be
580 higher than that of the AFT closure temperature (110 ± 10 °C) (Ge et al., 2016).
581 Moreover, the Re-Os age derived from the pyrobitumen of the Micang Shan Uplift in
582 this study is significantly older than the AFT dates, which further supports that the
583 closure temperature of the Re-Os systematics in pyrobitumen is higher than that of the
584 AFT closure temperature.

585 Deep burial and complex tectonic events have greatly affected the hydrocarbon
586 systems in the Sichuan Basin, and even the whole of the south China block, resulting
587 in gas being the main hydrocarbon resource (Zhao et al., 2004). The Re-Os data from
588 this study imply that the gas in the Sichuan Basin formed during the Latest Triassic to
589 the Middle Jurassic by thermal cracking. As such, the areas that have been relatively
590 tectonically stable since the Mesozoic, e.g., in the ancient uplift or slope in the central
591 and eastern Sichuan Basin (Zou et al., 2014a), may be prospective gas targets.

592 In addition to South China, pyrobitumen occurs worldwide, e.g., in the Alberta Basin,
593 Canada (Stasiuk, 1997), the Dahoney Basin, Nigeria (Meyer and De Witt Jr, 1990)
594 and the Basque-Cantabrian Basin, Spain (Agirrezabala et al., 2008). Thus, Re-Os
595 pyrobitumen chronology (coupled with AFT dating) could be employed to yield
596 quantitative timing of gas generation in other basins worldwide, and may enhance our
597 understanding of the evolution of hydrocarbon systems and help guide gas

exploration.

Chuanbo Shen (Corresponding author) is currently a professor in the Faculty of Earth Resources at the China University of Geosciences (Wuhan). He received his B.Sc., M.Sc., and Ph.D. from China University of Geoscience (Wuhan). He also completed postdoctoral research in Technische Universität Bergakademie Freiberg, Germany. His present research interests are low-temperature thermochronology, tectonic-thermal evolution and hydrocarbon geochronology.

David Selby

Department of Earth Sciences, Durham University, Durham, DH1 3LE, UK

david.selby@durham.ac.uk

David Selby is a Professor of Earth Sciences at Durham University, UK. He received a bachelor's degree in geology from Southampton University, UK and Ph.D. degree from the University of Alberta, Canada. He also carried out his postdoctoral research at the University of Alberta. His research focuses on the Earth Science disciplines of economic geology, petroleum geoscience and paleoclimate / oceanography, principally through the application and development of the novel, state-of-the-art, rhenium-osmium radio isotope methodology.

Guozhi Wang

Faculty of Earth Sciences, Chengdu University of Technology, Chengdu, 610059,

1168 China; No.1 Erxianqiao road, Chenghua District, Chengdu City, Sichuan Province,
1169 China.

1170 wangguozhi66@163.com

1171 Guozhi Wang is a Professor of the Earth Science Faculty of the Chengdu University
1172 of Technology. He obtained his bachelor degree from Chuangchun Geological College
1173 in 1986, and M.Sc degree and Ph.D from Chengdu University of Technology in 1989
1174 and 2000, respectively. His present research interests include basin analysis, isotopic
1175 dating, structure analysis of orogenic belts and sedimentary basins.

1176 **Zhao Yang**

1177 Department of Geology, Northwest University, Xi'an, 710069, China, No.229 North

Fig. 1. Simplified map of the Sichuan Basin showing the distribution of oil and gas fields (Substantially modified from Li et al., 2015; Li et al., 2001; Ma et al., 2010).

Fig. 2. Simplified geological map of the Micang Shan Uplift, northern Sichuan Basin.

(A) Regional map of the Micang Shan Uplift and its adjacent area, Longmen Shan Orogeny, Hannan Uplift and Daba Orogen in the west, northeast, east, respectively. (B)

Simplified geologic and structural map of Micang Shan Uplift, northern Sichuan Basin (Substantially modified from Wang et al., 2014), showing the location of both bitumen and the AFT samples.

Fig. 3. Combined stratigraphic sequences, petroleum system and tectonic events in the northern Sichuan Basin (Substantially modified from Huang, 2013; Huang, 2010; Wang, 2015).

Fig. 4. Examples of pyrobitumen outcropping in the Jiulingzi (JLZ), Nanmushu (NMS), Kongxigou (KXG) and Yangba (YB) areas.

Fig. 5. Petrography of the pyrobitumen of this study: (A) and (B) from the Nanmushu 1070 area; (C) and (D) from the Nanmushu 1030 area; and (E) and (F) from the Jiulingzi area.

Fig. 6. A. Re-Os isochron plot showing all the data in the Micang Shan Uplift; B. Plot of percent deviation from the 239 Ma best-fit line; C. Re-Os isotope data of bitumen from Mayuan, Nanmushu and Zhujiaba area with Os_{239} from 2.25 - 2.30. Data-point ellipses shown with 2-sigma (2σ) absolute uncertainty (sigma (σ) is the standard deviation of the age). MSWD is short for Mean Square Weight Deviation. Data labels are sample numbers listed in Table 1.

Fig. 7. Collected apatite fission track (AFT) thermal history modeling results from the Micang Shan Uplift and inner Sichuan Basin (Substantially modified from Tian et al., 2012; Yang et al., 2013). D: determined apatite fission track age; M: modeled apatite fission track age; GOF: goodness of fit; N: number of measured fission track; Lm: mean length of the measured fission track length; SD: standard deviation.

1234 Fig. 8. A. Basin modelling and fluid inclusion results for the Micang Shan Uplift,
1235 showing the key time for gas generation. B. Cartoon model showing the hydrocarbon
1236 evolution of the Micang Shan Uplift, north Sichuan Basin: (a) original hydrocarbon
1237 reservoir formation process prior to the Silurian; (b) pyrobitumen and dry gas
1238 formation by thermal cracking during the Jurassic; and (c) reservoir alteration and
1239 erosion during the Cretaceous Yanshan orogeny.
